Abstract

Purpose: To study the effect of inhaled cannabis on intraocular pressure (IOP) in healthy adult subjects. **Design:** Prospective, double-blind, randomized, placebo-controlled trial. **Methods:** Study participants were randomized to receive a single dose of inhaled cannabis or placebo in an 11:3 ratio. Subjects self-administered inhaled cannabis or placebo cigarette in negative-pressure rooms. Measurements of IOP, systemic blood pressure, and plasma tetrahydrocannabinol levels were taken at baseline and every 40 minutes for 2 hours, and afterwards, every hour for 3 hours. Paired T-test was performed on the IOP readings to compare the treatment group with the placebo group, and with baseline readings. **Results:** A total of 14 participants were included. Average baseline IOP for the treatment group and placebo group was 17.5 mmHg and 18.4 mmHg, respectively. IOP was significantly lowered from baseline in the treatment group at all time points post-treatment, up to the 4-hour time point. The placebo group had extensive IOP fluctuations and had a significant IOP reduction only at the 80-minute, 3-hour, and 5-hour time points. IOP was not significantly different between placebo and treatment groups. Peak IOP lowering occurred at the 80-minute time point with 15.7% reduction in IOP in the treatment group. There were no significant changes in systemic blood pressure during the duration of the study. **Conclusions:** Cannabis lowers IOP significantly from baseline in adult healthy subjects. This effect is detected from 40 minutes post-treatment and lasts up to 4 hours. Systemic blood pressure was not significantly affected.

The effect of cannabis on intraocular pressure (IOP) has long been a subject of speculation. Indeed, the first legal use of cannabis for any medical purpose in the USA was granted for the treatment of a patient with glaucoma in 1976. In the half century since then, only a few small studies have attempted to characterize the effects of cannabis on IOP. Cannabis is a genus of flowering plants in the Cannabaceae family, which consists of three primary species: *Cannabis sativa*, *Cannabis indica*, and *Cannabis ruderalis*. Cannabis contains more than 480 different compounds, of which, more than 100 have been identified as phytocannabinoids, including cannabidiol (CBD), and tetrahydrocannabinol (Δ^9 -THC).^{1,2} Cannabis is classified as a schedule 1 drug by the USA Drug Enforcement Administration (along with heroin and LSD [lysergic acid diethylamide]). Accordingly, there are many barriers to research involving cannabis and its derivatives on human subjects.³

Early, non-randomized studies in the 1970s and early 1980s showed that inhaled cannabis lowered IOP by about 25%, and this effect was shown to last between 2 and 4 hours.⁴ A study by Cooler and Greg in 1977, using intravenously injected THC in 10 human subjects, found that IOP was lowered by an average of 37%.⁵ Topically-applied THC has been shown to reduce IOP by 28% in a recent animal study, whereas topical CBD was shown to elevate IOP.⁶ Another small study suggested that sublingually-administered THC lowered IOP for up to 4 hours in a group of six human subjects.⁷ Although these, and other published studies, have confirmed that THC lowers IOP, this has not translated to the adoption or use of THC in clinical practice. There are many reasons for this. Firstly, cannabis is a psychoactive drug and systemic administration poses limitations for most patients. In addition, other side effects, such as tachycardia and elevated systolic blood pressure, have been reported.⁸⁻¹⁰ Topically-delivered formulations have historically poor penetration through the cornea, and resultant lack of efficacy.^{11,12} Hence, our understanding of the impact of cannabis on IOP in humans has been limited to these scant reports in the literature over the decades. This is the first prospective, randomized, double-blind, placebo-controlled study evaluating the effect of inhaled cannabis on IOP in healthy human subjects.

<1>Methods

<2>Regulatory process

This study was approved by the by the University of California, San Diego Human Research Protections, and was in accordance with the Helsinki Declaration and informed consent was obtained from all participants. The parent study was conducted under IND 131268, and approved by the Research Advisory Panel of California. This study was conducted at the University of California, Center for Medicinal Cannabis Research (CMCR). Two rooms were specifically outfitted with a negative-pressure system to enable cannabis to be vented to the atmosphere without contaminating the workspace of others. Cannabis was harvested at the University of Mississippi under the supervision of the National Institute on Drug Abuse (NIDA). Bulk placebo was made from whole plant with extraction of cannabinoids, in particular THC, and has the natural smell and appearance of the active cannabis.

<2>Participant selection

Participants were a consecutive subset of individuals enrolled in a larger study examining the impact of acute cannabis ingestion on driving performance. Participants were recruited from the community. Eligible participants were scheduled for a baseline session and one, 8-hour experimental session at the CMCR.

Patients had to be older than 21 years, a licensed driver and driven a minimum of 1,000 miles in the past year, a regular cannabis smoker (≥ 4 times in the past month), willing to not disclose details of the simulator and iPad-based assessments, and willing to complete the IOP tonometer evaluations. Exclusion criteria included a known history of glaucoma or other eye disorder other than refractive error; the inability to not use contact lenses on the day of visits; history of traumatic brain injury; an unwillingness to abstain from cannabis for 2 days prior to screening visit (so driving simulation will not be impaired) and 2 days prior to experimental visit (2–3 half-lives of THC); a positive pregnancy test; and a positive result on toxicity screening for cocaine, amphetamines, opiates, and phencyclidine (PCP). However, a positive result for a prescribed or recommended drug (cannabis) was not exclusionary. Individuals with current substance use

disorders, as assessed using the Drug Abuse Screening Test (DAST) and Alcohol Use Disorders Identification Test (AUDIT), were excluded. Subjects were also excluded for being unwilling to be transported by cab or have a responsible adult drive them home after experimental session or inability to complete study procedures (i.e., poor veins, unwillingness to be transported home by taxi or friend).

<2>Study design

A sub group of participants, from the parent study of 300 participants, was screened and enrolled for this IOP sub analysis. At the beginning of the screening/baseline visit and the experimental visit, subjects underwent a urine drug screen and breathalyzer for alcohol and drugs. In addition, an oral fluid sample was run for the presence of Δ^9 -THC using a testing device (Dräger DrugTest® 5000, Dräger, Lübeck, Germany) which identifies THC levels at above versus below 5 ng. A positive reading on the Draeger was considered indicative of use within the past day. Any participants with a positive reading were excluded (none occurred within the subsample for this study).

Participants were divided into two groups, each receiving either 5.9% or 13.4% Δ^9 -THC, or placebo cannabis cigarettes at their visits. Groups were assigned using a permuted-block randomization with stratification by prior cannabis exposure (frequent user [more than four times per week] versus occasional user [less than four times per week]). Participants were given 700 mg cigarettes with either 0% (placebo), or 5.9% or 13.4% Δ^9 -THC (treatment drug) at the beginning of the day and were instructed to “smoke the cigarette the way you do at home to get high” (i.e., there was no requirement that they finish the entire cigarette). Though not mandatory to incinerate the cigarette to the proximal tip, a minimum of four puffs was required for a participant to remain in the study. They were allowed 10 minutes to smoke. The allocation schedule was kept in the pharmacy and concealed from other study personnel. Patients and assessors were blinded to group assignments. IOP, complete driving simulations, iPad-based performance assessments, and bodily fluid draws (e.g., blood, oral fluid saliva, breath) were measured before the cannabis smoking and over the subsequent 6 hours after cannabis smoking.

<2>Monitoring of vital signs

Vital signs were checked at hourly intervals to monitor the subjects' health status as well as to quantify the general effects of the cannabis. At any sign of an adverse reaction (e.g., a change in blood pressure or pulse rate, or development of psychological distress), an investigator was called. Subjects remained in the laboratory under direct observation for 7 hours after the smoking inhalations were completed. At that time, a final vital sign and self-report status check was made, and upon satisfactory readings, the subject was released and driven back to their domicile by taxicab or prearranged transportation. The return transport procedure was observed directly by staff to ensure compliance.

<2>Cardiovascular monitoring

Blood pressure and pulse were assessed pre-smoking, and at approximately every 30 minutes for 2 hours post smoking session, then up to every hour for the additional 3 hours.

<2>Intraocular pressure measurements

IOP measurements were taken using the non-contact Ocular Response Analyzer® (Reichert Technologies, Depew, NY, USA). This device is FDA-approved and was used in accordance with the FDA label. Three IOP readings were taken for each eye prior to smoking, and then at approximately 40 minutes, 80 minutes, 120 minutes, and every hour for the additional 3 hours after smoking. IOP readings were obtained by trained research assistants. If the participant had high IOP (≥ 21 mmHg) prior to smoking, we recommended follow-up with an ophthalmologist.

<1>Results

Data from 28 eyes (14 patients) were analyzed. The age range of study participants was 21–55 years. The data were divided into two groups: treatment (n=22 eyes) and placebo (n=6 eyes). There were no missing values or outliers in the data. Because the participants were allowed to smoke a discretionary amount to achieve psychotropic effects, the low-dose and high-dose group had similar plasma levels of THC and were therefore grouped together in one treatment group.

Three IOP readings were taken at each time point from each subject and the average of these readings was obtained for each time point. The IOP was normally distributed. For each group, a paired t-test was conducted to test for statistical difference at each time point compared with baseline.

In the treatment group, the IOP reduction was statistically significant at all time points after treatment, up to and including the 4-hour post treatment. There was also a significantly lowered IOP in the placebo group, but this was only seen at variable intervals: at the 80-minute, 3-hour, and 5-hour time points. There were no statistically significant differences in the IOP-lowering observed between the placebo and treatment groups.

<1>Discussion

The results of this study indicate that in healthy adult subjects, inhaled cannabis significantly lowers IOP, and that this effect is detected within 40 minutes of inhalation. This IOP lowering of about 15% slowly drifted back towards baseline, but the effects were still significant at 4 hours post treatment dosing (*Figure 1*). Interestingly, the placebo group also saw a reduction in IOP after dosing; however, the IOP effect was less dramatic, and more labile. There are several reasons for this.

First, there was a very small sample of participants in the placebo group, leading to less robust powering of the placebo arm. Second, the baseline IOP was lower in the treatment group (17.5 mmHg) compared to baseline IOP in the placebo group (18.4 mmHg). Starting at a lower IOP limits the potential for further IOP reduction and skews the data such that a significant difference is more difficult to establish. There may be also have been an additional effect of relaxation imparted to the placebo group, as the treatment was self-administered in a quiet room without interruptions. It has been shown that endocannabinoid system can elicit a strong placebo effect which can be activated by the smell of cannabis and visual cues associated with smoking cannabis, such as the cigarette itself, the smoke, or the lighter.¹³ It can be assumed that when smoking what the subject understands might contain cannabis, that a certain degree of

expectation and relaxation is imparted, activating the endocannabinoid system, in turn, eliciting the placebo effect on IOP.

Additionally, a recent study by Dada et al. concluded that a 21-day practice of relaxation and mindful meditation can lower IOP by 25%.¹⁴ Lastly, and perhaps most importantly, there is a known effect of placebo on IOP.¹⁵ A recent article by Sharpe et al. reviewed the placebo-group IOP data from 23 clinical trials and found that in 22 of the trials, there was a significant effect of placebo on IOP, sometimes as much as 2 mmHg, similar to our findings, as summarized in *Figure 2*. Another meta-analysis of phase I/II glaucoma clinical trials investigating the placebo effect on IOP, found that IOP reduction from baseline was less pronounced in the treatment group than in the placebo group in all 50 studies reviewed. The authors concluded that in early-phase clinical trials, the reduction from baseline better approximates the results of later regulatory and post-commercialization trials than the decrease from placebo.¹⁵

The specific mechanisms by which cannabis lowers IOP are the subject of active investigation. It is known that there are cannabinoid receptors located throughout the eye, in particular in the ciliary muscle, ciliary epithelium, trabecular meshwork, and Schlemm's canal.¹⁶ These receptors, part of the endocannabinoid system, include CB1, CB2, GPR18, GPR119, and GPR55. It has been shown, in mouse models, that CB1, GPR18, and GPR119 each lower IOP when activated by topical administration of Δ^9 -THC.⁵ This study also found that CBD blocks THC from lowering IOP, hence the active IOP-lowering component of cannabis is Δ^9 -THC, and not CBD.

Studies have found that CB1 activation results in a series of varied changes, such as ciliary body contraction, widening of Schlemm's canal, and activation of matrix metalloproteinase, which enhances outflow of the trabecular meshwork.^{17,18} Moreover, cannabinoids not only act through the CB1 pathway, but also activate COX-2, which increases the presence of prostaglandin E2 and metalloproteinases, enhancing the outflow of aqueous humor and thereby reducing IOP.^{19,20} It has also been suggested that some cannabinoids lower IOP through a prostaglandin-mediated mechanism, as well as through adrenergic receptors within the eye.²¹⁻²³ There is a possibility that

cannabis may enhance ocular blood flow and perhaps perfusion to the optic nerve. This was suggested by a study investigating the effect of oral dronabinol in healthy volunteers, which showed decreased retinal arterio-venous passage time, as measured by fluorescein angiography.²⁴ Besides any manipulation on ocular blood flow, the potential role of cannabis in neuroprotection has been suggested by many studies, although no clear evidence of neuroprotection in glaucoma has yet been established.^{25,26}

Aside from psychotropic effects, another potential limitation to the use of systemically administered cannabis is the purported effect on systemic blood pressure. The cardiovascular effects of cannabis are not well understood as they appear to be variable and heterogeneous. Cannabis consumption has been shown to cause an increase in systolic blood pressure, while potentiating orthostatic hypotension and tachycardia.²⁷ The ultimate effect of cannabis on perfusion pressure to the optic nerve remains unknown at this time. Data from the treatment group in the current study showed no significant effect on systolic blood pressure at any time point, and only one statistically significant diastolic blood pressure reading at the 120-minute post-dose measurement, which is not clinically significant, nor statistically different from placebo (*Figures 3 and 4*). These data did not raise any new concerns with regards to short-term cardiovascular side effects in healthy individuals.

Given the wide range of systemic considerations, the routine use of inhaled or ingested cannabis for glaucoma treatment is not generally feasible. However, novel compounds with improved corneal penetration are being developed for topical administration, thereby mitigating systemic side-effects.^{28,29} In addition, non-psychotropic cannabinoids and other CB1 receptor targets are being investigated for potential treatments that avoid systemic effects.^{30,31}

There are several limitations to this study. First, the number of subjects in the placebo group was small and may have introduced error into the results from the natural variability in IOP during the diurnal period. Second, the method of obtaining the IOP data was through a non-contact tonometry method in order to facilitate the acquisition of IOP data in contact lens wearers, and

decrease the invasiveness of measurements for this pilot study. Ideally, future studies should use more consistently accurate methods of tonometry. In addition, this study only involved healthy adults, and does not characterize the IOP-lowering effects of cannabis in subjects with glaucoma, ocular hypertension, or in subjects with concomitant IOP-lowering medications.

In conclusion, the current study demonstrates robust IOP reduction with inhaled cannabis in healthy adults that is sustained for up to 4 hours, with no significant effect on cardiovascular parameters. Defining the role of cannabis in glaucoma treatment requires further studies to better characterize these effects in different patient populations.
